

PATH TRANSFORMATIONS FOR LOCAL TIMES OF ONE-DIMENSIONAL DIFFUSIONS

UMUT ÇETIN

ABSTRACT. Let X be a regular one-dimensional transient diffusion and L^y be its local time at y . The stochastic differential equation (SDE) whose solution corresponds to the process X conditioned on $[L_\infty^y = a]$ for a given $a \geq 0$ is constructed and a new path decomposition result for transient diffusions is given. In the course of the construction of the SDE the concept of *recurrent transformation* is introduced and *Bessel-type motions* as well as their SDE representations are studied. A remarkable link between an h -transform with a minimal excessive function and recurrent transformations is found, which, as a by-product, gives a useful representation of last passage times as a mixture of first hitting times. Moreover, the Engelbert-Schmidt theory for the weak solutions of one dimensional SDEs is extended to the case when the initial condition is an entrance boundary for the diffusion. This extension was necessary for the construction of the Bessel-type motion which played an essential part in the SDE representation of X conditioned on $[L_\infty^y = a]$.

1. INTRODUCTION

Conditioning a given Markov process, X , is a well-studied subject which has become synonymous with the term *h-transform*. If one wants to condition the paths of X to stay in a certain set, the classical recipe consists of finding an appropriate excessive function, h , defining the transition probabilities of the conditioned process via h , and constructing on the canonical space a Markov process, X^h , with these new transition probabilities using standard techniques. This procedure is called an h -transform and its origins go back to Doob and his study of boundary limits of Brownian motion [4, 5]. If h is a minimal excessive function with a pole at y (see Section 11.4 of [3] for definitions), then X^h is the process X conditioned to converge to y and killed at its last exit from y . We refer the reader to Chapter 11 of [3] for an in-depth analysis of h -transforms and their connections with time reversal and last passage times.

If X is regular transient diffusion taking values in some subset of \mathbb{R} , $h := u(\cdot, y)$ is a minimal excessive function for every y in its state space, where u is the potential density of X . Moreover, y is the unique pole of this excessive function. Thus, the preceding discussion suggests that this h -transform condition X to converge to y and kills it at its last exit from y . For a thorough discussion of h -transforms for one-dimensional diffusions and the proofs of certain results that are considered to be folklore in the literature we refer the reader to a recent manuscript by Evans and Hening [7]. The recent work of Perkowski and Ruf [15] also considers a specific case of conditioning for one-dimensional diffusions.

Date: March 8, 2016.

In this paper we are interested in conditioning a one-dimensional regular transient diffusion on the value of its local time at its lifetime. We assume that the diffusion cannot be killed in the interior of its state space. It is well-known that (X, L^y) is a two-dimensional Markov process, where L^y is the local time of X at level y . If we would like to apply an h -transform to achieve our conditioning, we need to find a minimal excessive function of the pair (X, L^y) with a suitable pole so that the local time of the X^h equals a given number, say, $a \geq 0$ at its lifetime. The problem with this approach is that it requires the knowledge of the potential density of the Markov pair (X, L^y) , which is in general not easily obtained or characterised. Moreover, as in every h -transform, it requires a killing procedure.

We shall follow a different approach and construct the conditioned process as a weak solution to a stochastic differential equation (SDE) with a suitably chosen drift. This obviously requires the original process, X , being a solution of an SDE. In Section 2 we impose the standard Engelbert-Schmidt conditions in order to ensure that X itself is the unique weak solution of an SDE upto a, possibly finite, exit time from its state space. Our aim is to construct an SDE –for which weak uniqueness holds– such that the law of its solutions coincides with the law of X conditioned on the null set $[L_\infty^y = a]$. As such, there will be no killing involved in the interior of the state space in our conditioning.

At the end of Section 2 we give a recipe for constructing the SDE with the above property and a brief warning about pitfalls that one may encounter depending on the limiting values of X . However, difficulties aside, the desired conditioning should be done in two steps: In Step 1 we have to choose a suitable drift that makes sure that the solution keeps hitting y until the local time process equals a . As soon as this is achieved, in Step 2, we have to choose a new drift that prevents the solutions hitting y again and, thus, keeping the local time process constant at a .

Since we want to make sure that $L_\infty^y = a$ with probability one for the conditioned process, it is necessary that we have to choose a drift term in Step 1 to transform X into a recurrent process. Indeed, if the solution of the SDE considered in Step 1 is transient, there is a non-zero probability for its solution to drift away to the cemetery state before its local time process hits a . To this end we introduce the concept of a *recurrent transformation* in Section 3. Roughly speaking, a recurrent transformation adds a drift term to the original SDE of X so that the resulting process is a regular diffusion with the same state space which it cannot exit in finite time. A particular example of a recurrent transformation will give us the drift that achieves the Step 1 of our conditioning procedure. Interestingly, this specific recurrent transformation will be intimately linked to the h -transform of X that we discussed at the beginning of this section with $h = u(\cdot, y)$, which conditions X to converge to y and kills it at its last exit from y . We show in Remark 3 that these particular examples of recurrent transformation and the h -transform produce diffusions with the same scale function and the speed measure. Yet the resulting diffusions are fundamentally different since one is transient while the other is recurrent. As one could expect the difference between the recurrent transformation and the h -transform lies in their killing measures. While the killing measure for the former is null, it is a Dirac measure for the latter. Given that they have the same scale function and the speed measure it is only natural to ask whether one can obtain the h -transform from the recurrent transformation via a killing. We show in Remark 3 that one can indeed get the h -transform by killing the recurrent transform at a random time

which is a mixture of inverse local times associated to the recurrent transformation. As a by-product of this result we also deduce that one can simulate the last passage times of a transient diffusion by simulating a mixture of the first hitting times of the local times of a related diffusion. This is not only a result of independent interest but it can be also useful in simulation studies involving last passage times of diffusions.

Section 4 prepares the drift terms that one would use in Step 2 of the conditioning procedure. Since the solution of the SDE at the end of Step 1 equals y , and the new drift should be chosen in a way to keep the conditioned process away from y , the drift term that must be employed in the second step of our construction leads to solutions that are linked to the excursions of X away from y . Indeed, if $y = 0$ and X is a Brownian motion killed at 0, the SDE that we obtain in Step 2 is the SDE associated to the 3-dimensional Bessel process. In Section 4 we give the SDE characterisations of these *Bessel-type motions* –a term adapted from McKean in his study of excursions of diffusions [12]– and prove a time reversal result akin to those that can be found in the seminal paper of Williams [20] using a theorem due to Nagasawa [14].

After all these preparations and the other related results of independent interest, the SDE that is associated to the desired conditioning is constructed in Section 5. Weak uniqueness of its solutions is proven in Theorem 5.1 and Corollary 5.2 establishes that the law of its solutions possesses the desired bridge property using an enlargement of filtration technique. Corollary 5.2 also paves the way for a new path decomposition result for transient diffusions. Theorem 5.2 is reminiscent of Williams' path decomposition for the Brownian motion killed at 0 and constructs the original process, X , by pasting together a recurrent transformation and a time-reversed Bessel-type motion.

Another contribution of this paper is to the solutions of one dimensional time-homogeneous SDEs. In Step 2 we construct an SDE for a one-dimensional diffusion, where the initial condition is an entrance boundary¹. The existence and uniqueness of solutions to such SDEs do not follow from the Engelbert-Schmidt theory, which constructs the solution from a time-changed applied to a Brownian motion. As explained in Section 2, the reason for the non-applicability of the available theory is due to the scale functions being infinite at entrance boundaries forcing one to start the Brownian motion at $+\infty$ if one want to use the method of Engelbert and Schmidt. Theorem 2.1 extends the Engelbert-Schmidt theory to the case when the initial condition is an entrance boundary. The proof uses similar tools employed in the proof of the classical result of Engelbert and Schmidt without the entrance boundary. However, we construct the weak solution as a time-changed Bessel process as opposed to a time-changed Brownian motion.

The outline of the paper is as follows. Section 2 reviews some background material on one-dimensional diffusions that will be used often in the paper and gives a recipe for the construction of the SDE to achieve our desired conditioning. Section 3 introduces the concept of recurrent transformation and finds the drift that will be necessary to complete Step 1. The drift term that will be used in the second step of our construction is discussed in Section 4 along with its connection to the excursions of X . Our main results on the SDE representation of X conditioned on its local time at its lifetime and a new path decomposition result for

¹In the terminology of Ito-McKean this corresponds to an entrance-not-exit boundary.

transient diffusions are contained in Section 5. Finally, Section 6 illustrates the findings via some specific examples.

2. PRELIMINARIES AND A RECIPE FOR THE CONDITIONING

Let X be a regular transient diffusion on (l, r) , where $-\infty \leq l < r \leq \infty$. Such a diffusion is uniquely characterised by its scale function, s , and speed measure, m , defined on the Borel subsets of the open interval (l, r) . We assume that if any of the boundaries are reached in finite time, the process is killed and sent to the cemetery state, Δ . This is the only instance when the process can be killed, we do not allow killing inside (l, r) . Consistent with the term ‘killing’ Δ is assumed to be an absorbing state. The set of points that can be reached in finite time starting from the interior of (l, r) and the entrance boundaries will be denoted by I . That is, I is the union of (l, r) with the regular, exit or entrance boundaries. The law induced on $C(\mathbb{R}_+, I)$, the space of I -valued continuous functions on $[0, \infty)$, by X with $X_0 = x$ will be denoted by P^x as usual, while ζ will correspond to its lifetime. In what follows we will often replace ζ with ∞ when dealing with the limit values of the processes as long as no confusion arises. The filtration $(\mathcal{F}_t)_{t \geq 0}$ will correspond to the universal completion of the natural filtration of X , and therefore is right continuous. Recall that in terms of the first hitting times, $T_y := \inf\{t > 0 : X_t = y\}$ for $y \in (l, r)$, the regularity amounts to $P^x(T_y < \infty) > 0$ whenever x and y belongs to the open interval (l, r) . This assumption entails in particular that s is strictly increasing and continuous (see Proposition VII.3.2 in [18]), thereby possessing a left derivative, s' , on (l, r) , and $0 < m((a, z)) < \infty$ for all $l < a < z < r$ (see Theorem VII.3.6 and the preceding discussion in [18]).

The hypothesis that X is transient implies that at least one of $s(l)$ and $s(r)$ must be finite. Since s is unique only upto an affine transformation, we will assume without loss of generality that $s(l) = 0$ and $s(r) = 1$ whenever they are finite. In view of our foregoing assumptions one can easily deduce that $X_{\zeta-} \in \{l, r\}$. We refer the reader to [2] for a summary of results and references on one-dimensional diffusions. The definitive treatment of such diffusions is, of course, contained in [8].

As we are interested in the path transformations of local times via SDEs, we further impose the so-called *Engelbert-Schmidt conditions* to ensure that X can be considered as a solution of an SDE. That is, we shall assume the existence of measurable functions $\sigma : (l, r) \mapsto \mathbb{R}$ and $b : (l, r) \mapsto \mathbb{R}$ such that for any $x \in (l, r)$

$$\sigma(x) > 0 \text{ and } \exists \varepsilon > 0 \text{ s.t. } \int_{x-\varepsilon}^{x+\varepsilon} \frac{1 + |b(y)|}{\sigma^2(y)} dy < \infty. \quad (2.1)$$

Under this assumption (see [6] or Theorem 5.5.15 in [9]) there exists a *unique* weak solution (upto the exit time from the interval (l, r)) to the SDE

$$X_t = x + \int_0^t \sigma(X_s) dB_s + \int_0^t b(X_s) ds, \quad t < \zeta,$$

where $\zeta = \inf\{t \geq 0 : X_{t-} \in \{l, r\}\}$ and $l < x < r$.

The Engelbert-Schmidt conditions ensure the existence and uniqueness of weak solutions to above SDE starting from $x \in (l, r)$. However, it should be noted that the results of the Engelbert-Schmidt do not apply if the starting point is an entrance boundary since the scale

function is not finite at such an endpoint. The following theorem, whose proof is delegated to the Appendix, extends this theory when x is an entrance boundary for a transient diffusion. A quick glance at the proof reveals that the solution is obtained as a time and scale change of a 3-dimensional Bessel process starting from its entrance boundary as opposed to the standard Engelbert-Schmidt theory that constructs the solution as a time and scale change of a Brownian motion.

Theorem 2.1. *Suppose that X is a regular transient diffusion on (l, r) with an entrance boundary and satisfies (2.1). Then there exists a unique weak solution to*

$$X_t = x + \int_0^t \sigma(X_s) dB_s + \int_0^t b(X_s) ds, \quad t < \zeta, \quad (2.2)$$

where $\zeta = \inf\{t \geq 0 : X_{t-} \in \{l, r\}\}$ and x is the entrance boundary.

We summarise the assumptions on X in the following

Assumption 2.1. *X is a regular transient diffusion on (l, r) , where $-\infty \leq l < r \leq \infty$. Moreover, whenever X_0 is an entrance boundary or belongs to (l, r) , X is the unique weak solution to*

$$X_t = x + \int_0^t \sigma(X_s) dB_s + \int_0^t b(X_s) ds, \quad t < \zeta, \quad (2.3)$$

where $\zeta = \inf\{t > 0 : X_{t-} \in \{l, r\}\}$, and $\sigma : (l, r) \mapsto \mathbb{R}$ and $b : (l, r) \mapsto \mathbb{R}$ satisfy (2.1) for all $x \in (l, r)$. Its scale function is chosen so that $s(l) = 0$ and $s(r) = 1$ whenever they are finite.

Observe that the condition (2.1) further implies one can take

$$s(x) = \int_C^x \exp\left(-2 \int_c^z \frac{b(u)}{\sigma^2(u)} du\right) dz \quad \text{and} \quad m(dx) = \frac{2}{s'(x)\sigma^2(x)} dx, \quad \text{for some } (c, C) \in (l, r)^2.$$

We will denote by $(L_t^x)_{x \in (l, r)}$ the family of diffusion local times associated to R . Recall that the occupation times formula for the diffusion local time is given by

$$\int_0^t f(X_s) ds = \int_l^r f(x) L_t^x m(dx).$$

From above one can easily deduce the relationship

$$\tilde{L}^x = \frac{2}{s'(x)} L^x, \quad (2.4)$$

where \tilde{L}^x is the semimartingale local time of X at x , when X is a semimartingale.

Remark 1. *It is clear from the above relationship that the diffusion local time is not invariant under absolutely continuous changes of measures, which change the scale function. In the sequel when we consider sets of the form $[L_T^x > a]$, where T is a stopping time, we shall always think of it as the set $[\tilde{L}_T^x > \frac{2}{s'(x)a}]$ written in terms of the semimartingale local time. Since the semimartingale local time can be defined as a limit involving the quadratic variation of X (see Corollary VI.1.9 in [18]), which remains intact after an absolutely continuous measure change.*

Any regular transient diffusion on (l, r) has a finite potential density, $u : (l, r)^2 \mapsto \mathbb{R}_+$, with respect to its speed measure (see p.20 of [2]). That is, for any bounded and continuous function, f , vanishing at accessible boundaries

$$Uf(x) := \int_0^\infty E^x[f(X_t)]dt = \int_l^r f(y)u(x, y)m(dy).$$

In the case of one-dimensional transient diffusions that we consider herein the distribution of L_∞^y is known explicitly in terms of the potential density (see p.21 of [2]). In particular,

$$P^y(L_\infty^y > t) = \exp\left(-\frac{t}{u(y, y)}\right). \quad (2.5)$$

Therefore, for an arbitrary starting point, x , in (l, r) and any Borel subset, E , of (l, r) we have

$$P^x(L_\infty^y \in E | \mathcal{F}_t) = \mathbf{1}_{[L_t^y \in E]}(1 - \psi(X_t, y)) + \frac{\psi(X_t, y)}{u(y, y)} \int_E \mathbf{1}_{[a > L_t^y]} \exp\left(-\frac{a - L_t^y}{u(y, y)}\right) da, \quad (2.6)$$

where

$$\psi(x, y) := P^x(T_y < \infty),$$

in view of the strong Markov property of X .

It will also prove useful in the sequel to consider the *inverse local time*:

$$\tau_a^y = \inf\{t \geq 0 : L_t^y > a\}.$$

$(\tau_a^y)_{a \geq 0}$ is right continuous and, moreover,

$$\tau_{a-}^y = \inf\{t \geq 0 : L_t^y \geq a\}.$$

Clearly, the interval $[\tau_{a-}^y, \tau_a^y]$ corresponds to an interval of constancy for L^y or, equivalently, an excursion of X from the point y .

When only one of $s(l)$ and $s(r)$ is finite, the terminal value of X equals either l or r , in which case X_∞ and L_∞^y are trivially independent no matter where the diffusion has started. If both $s(l)$ and $s(r)$ are finite, the situation is more delicate. The following result that illustrates this must be well-known. We nevertheless provide a proof for the convenience of the reader.

Proposition 2.1. *Suppose that X is a regular transient diffusion on (l, r) with $s(l) = 0 = 1 - s(r)$. Then, X_∞ and L_∞^y are independent under P^x if and only if $x = y$.*

Proof. Suppose that $x \leq y$ and observe from (2.6) that

$$P^x(L_\infty^y > t) = P^x(T_y < \infty) \exp\left(-\frac{t}{u(y, y)}\right).$$

Next, consider the h -transform of X using s as the h -function to obtain a diffusion with transition function

$$P_t^s(x, dz) = \frac{s(z)}{s(x)} P_t(x, dy),$$

where P_t is the original transition function of X . The resulting process corresponds to the conditioning of X so that $X_\infty = r$ and it is a regular diffusion on (l, r) with the speed measure, m^s , and the potential density² u^s given by (see Paragraph 31 in Chap. II of [2])

$$m^s(dz) = s^2(z)m(dz) \quad u^s(x, z) = \frac{u(x, z)}{s(x)s(z)}.$$

Denoting the law of the h -transform with $P^{h,x}$ when it starts at x , we have, in particular,

$$P^{h,x}(L_\infty^y > t) = P^x(L_\infty^y > t | X_\infty = r).$$

Notice that, since the speed measure has changed, the diffusion local time of the h -transform is no longer represented by L^y . Let $L^{s,x}$ denote the diffusion local time with respect to m^s at the level x . In view of the occupation times formula and the fact that $P^{h,x} \sim P^x$ on \mathcal{F}_t one has

$$\int_l^r f(x) L_t^x m(dx) = \int_0^t f(R_s) ds = \int_l^r f(x) L_t^{s,x} s^2(x) m(dx),$$

which yields $\frac{L_t^y}{s^2(y)} = L_t^{s,y}$ due to the continuity of local times. Since L_t^y converges to L_∞^y under P^x , so it does under $P^{s,x}$ since $P^{s,x} \ll P^x$. Therefore, $\frac{L_\infty^y}{s^2(y)} = L_\infty^{s,y}$ and

$$P^x(L_\infty^y > t | X_\infty = r) = P^{h,x}\left(L_\infty^{s,y} > \frac{t}{s^2(y)}\right) = \exp\left(-\frac{t}{s^2 u^s(y, y)}\right) = \exp\left(-\frac{t}{u(y, y)}\right),$$

since $P^{s,x}(T_y < \infty) = 1$ due to the conditioning. Thus,

$$P^x(L_\infty^y > t | X_\infty = r) = P^x(L_\infty^y > t)$$

if and only if $x = y$. The case $x \geq y$ is handled similarly by conditioning on $[X_\infty = l]$ using the h -function $1 - s$. \square

Note that if $s(l) = 0 = 1 - s(r)$, then $P^x(X_\infty = r) = s(r)$ and

$$\psi(x, y) = \begin{cases} \frac{s(x)}{s(y)}, & y \geq x; \\ \frac{1-s(x)}{1-s(y)}, & y < x. \end{cases} \quad u(x, y) = s(x)(1 - s(y)), \quad x \leq y. \quad (2.7)$$

On the other hand, if $s(l) = 0$ and $s(r) = \infty$, then $X_t \rightarrow l$, P^x -a.s. for any $x \in (l, r)$, which in turn implies

$$\psi(x, y) = \begin{cases} \frac{s(x)}{s(y)}, & y \geq x; \\ 1, & y < x. \end{cases} \quad u(x, y) = s(x), \quad x \leq y. \quad (2.8)$$

Similarly, if $s(l) = -\infty$ and $s(r) = 1$, then $X_t \rightarrow r$, P^x -a.s. for any $x \in (l, r)$, and

$$\psi(x, y) = \begin{cases} 1, & y \geq x; \\ \frac{1-s(x)}{1-s(y)}, & y < x. \end{cases} \quad u(x, y) = 1 - s(y), \quad x \leq y. \quad (2.9)$$

For later purposes we also define

$$\rho(y) := P^y(X_\infty = r). \quad (2.10)$$

²Note that this is the density with respect to the new speed measure m^h .

We are interested in conditioning X so that $L_\infty^y = a$ for some given $a > 0$. As any such conditioning will make sure that X first hits y , we will assume $X_0 = y$ to ease the exposition. Formally, the construction of the conditioned process should be achieved in two steps: 1) make sure that X keeps hitting y before L^y reaches a and 2) as soon as L^y becomes a never let X hit y again.

In order to achieve the first step we need to change the behaviour of X in such a way that the process is *recurrent*. Indeed, if X is still transient after some transformation, there will be a positive probability that it will drift towards one of its endpoints before L^y becomes a . In Section 3 we will introduce the concept of a *recurrent transformation* and consider a particular example which allows us to complete the first step of our conditioning.

The second step in our recipe is to prevent X from hitting y after τ_{a-}^y . Since $X_{\tau_{a-}^y} = y$, on $[\tau_{a-}^y < \infty]$, this means that we need to keep X above or below y after τ_{a-}^y . Recall that we are not merely interested in creating a process with the property that $L_\infty^y = a$, but a conditioned version of X whose law coincides with the regular conditional probability $P^y(\cdot | L_\infty^y = a)$. This necessitates, in particular, that the conditioned process should also have the same set of possible values for its limiting value. If $s(l) = 0$ and $s(r) = \infty$ (resp. $s(l) = -\infty$ and $s(r) = 1$), our task is relatively simple: keep X below (resp. above) y at all times after τ_{a-}^y .

On the other hand, if $s(l) = 0 = 1 - s(r)$, the original process could drift towards r as well as l . As we are only conditioning on L_∞^y and not on X_∞ , we will have to appropriately randomise the coefficients of the SDE for the bridge process to allow our solution have l and r as possible limit points. In Section 4 we study the *Bessel-type* SDEs with appropriate drifts that will allow us to complete the second step, discuss its connection with the excursions of X , and present a time reversal connection. Finally, the SDE that achieves our desired conditioning with randomised drifts is constructed in Section 5.

3. RECURRENT TRANSFORMATIONS AND STEP 1

The first step towards our desired conditioning requires us transform X into a recurrent diffusion. To wit, suppose h is a non-negative C^2 -function and M an adapted continuous process of finite variation so that $h(X)M$ is a non-negative local martingale. Thus, by stopping at its localising sequence and using Girsanov's theorem we arrive at a weak solution, up to a stopping time, of the following equation for any given $y \in (l, r)$ taking values in (l, r) :

$$X_t = y + \int_0^t \sigma(X_s) dB_s + \int_0^t \left\{ b(X_s) + \sigma^2(X_s) \frac{h'(X_s)}{h(X_s)} \right\} ds. \quad (3.11)$$

We can associate to this SDE the scale function

$$r_s(x) := \int_c^x \frac{s'(y)}{h^2(y)} dy, \quad x \in (l, r) \quad (3.12)$$

provided that the integral is finite for all $x \in (l, r)$, which, in particular, requires $h > 0$ on (l, r) . This will allow us to deduce the existence of a solution to (3.11) until the first exit time from (l, r) . If, in addition, $-r_s(l+) = r_s(r-) = \infty$, the solution will be recurrent and never exit (l, r) (see Proposition 5.5.22 in [9]).

Remark 2. *It has to be noted that the notion of recurrence that we consider for one-dimensional diffusions excludes some recurrent solutions of one-dimensional SDEs with time-homogeneous coefficients since we kill our diffusion as soon as it reaches a boundary point. A notable example is a squared Bessel process with dimension $\delta < 2$, which solves the following SDE:*

$$X_t = y + 2 \int_0^t \sqrt{X_s} dB_s + \delta t.$$

The above SDE has a global strong solution, i.e. solution for all $t \geq 0$, which is recurrent (see Section XI.1 of [18]). However, the point 0 is reached a.s. and is instantaneously reflecting by Proposition XI.1.5 in [18]. As such, it violates our assumption of a diffusion being killed at a regular boundary. According to this assumption, a squared Bessel process of dimension $0 < \delta < 2$ is killed as soon as it reaches 0 and, thus, is a transient diffusion.

Using h and M to get a recurrent process imposes some boundary conditions on h . Indeed, if $s(l) = 0$ (resp. $s(r) = 1$), in order to have $r_s(l+) = -\infty$ (resp. $r_s(r-) = \infty$), we must have $\lim_{x \rightarrow l} h(x) = 0$ (resp. $\lim_{x \rightarrow r} h(x) = 0$).

Moreover, since $h(X_t)M_t$ is a local martingale, $dM_t = -M_t \frac{Ah(X_t)}{h(X_t)} dt$. Thus, M is a multiplicative functional³ given by

$$M_t = \exp \left(- \int_0^t \frac{Ah(X_s)}{h(X_s)} ds \right).$$

In the light of the above discussion we now introduce the concept of a *recurrent transformation of a diffusion*.

Definition 3.1. *Let X be a regular transient diffusion satisfying Assumption 2.1 and $h : (l, r) \mapsto (0, \infty)$ be a continuous function such that the limits $h(l+) := \lim_{x \rightarrow l} h(x)$ and $h(r-) := \lim_{x \rightarrow r} h(x)$ exists. Then, (h, M) is said to be a recurrent transform (of X) if the following are satisfied:*

- (1) *M is an adapted process of finite variation.*
- (2) *$h(X)M$ is a nonnegative local martingale.*
- (3) *The function r_s from (3.12) is finite for all $x \in (l, r)$ with $-r_s(l+) = r_s(r-) = \infty$.*
- (4) *There exists a unique weak solution to (3.11) for $t \geq 0$.*

In the above definition, the defining condition for a recurrent transformation is the function r_s and its explosive nature near the boundaries. The function h and the multiplicative functional M come into play when one wants to construct a weak solution of the SDE (3.11) and show that the law of its solution is locally absolutely continuous with respect to that of the original process X , which satisfies (2.3), as in Proposition 3.1.

Theorem 3.1. *Let $h : (l, r) \mapsto (0, \infty)$ be an absolutely continuous function such that its left derivative, h' , is of finite variation. Suppose further that the mapping r_s given by (3.12) is finite for all $x \in (l, r)$ and that $-r_s(l+) = r_s(r-) = \infty$. Then, the following statements are valid.*

³See Section 1 of Chapter III and the rest in [1] for a definition and properties. We will not need any further properties of multiplicative functionals in this paper.

- (1) h' admits the decomposition $dh'(x) = h''(x)dx + n(dx)$, where n is a locally finite signed measure on (l, r) that is singular with respect to the Lebesgue measure.
- (2) The integral

$$\mathbf{1}_{[t < \zeta]} \left(\int_0^t |Ah(X_s)| ds + \int_l^r L_t^x \frac{1}{s'(x)} |n(dx)| \right) < \infty, \text{ } P^y\text{-a.s.},$$

for every $y \in (l, r)$, where $Ah = \frac{\sigma^2(x)}{2}h''(x) + b(x)h'(x)$ with an abuse of notation.

- (3) (h, M) is a recurrent transform, where, on $[t < \zeta]$,

$$M_t := \exp \left(- \int_0^t \frac{Ah(X_s)}{h(X_s)} ds - \int_0^t \frac{1}{h(X_s)} d\Lambda_s(h) \right) \text{ and}$$

$$\Lambda_t(h) := \int_l^r L_t^x \frac{1}{s'(x)} n(dx).$$

- (4) Let $R^{h,y}$ be the law of the solution of (3.11) and $\Gamma \in \mathcal{F}_T$ for some (\mathcal{F}_t) -stopping time, T , such that $h(X^T)M^T$ is a uniformly integrable P^y -martingale. Then,

$$R^{h,y}(\Gamma) = \frac{1}{h(y)} E^y [\mathbf{1}_\Gamma h(X_T) M_T]. \quad (3.13)$$

Proof. (1) The decomposition follows from Theorem 0.4.4 in [18].

- (2) Observe that, in view of occupation times formula, the integral on $[t < \zeta]$ equals

$$\begin{aligned} & \int_l^r \left| \frac{\sigma^2(x)}{2} h''(x) + b(x)h'(x) \right| L_t^x \frac{2}{s'(x)\sigma^2(x)} dx + \int_l^r L_t^x \frac{1}{s'(x)} |n(dx)| \\ &= \int_l^r \left| h''(x) + \frac{2b(x)}{\sigma^2(x)} h'(x) \right| L_t^x \frac{1}{s'(x)} dx + \int_l^r L_t^x \frac{1}{s'(x)} |n(dx)| \end{aligned}$$

Due to the continuity of X , on $[t < \zeta]$ and on almost every path L_t^x would be equal to 0 for all x outside a compact interval in (l, r) determined by the maximum and the minimum of X on $[0, t]$. Moreover, due to the continuity of $x \mapsto L_t^x$, it suffices to check

$$\int_K \left| h''(x) + \frac{2b(x)}{\sigma^2(x)} h'(x) \right| \frac{1}{s'(x)} dx + \int_K \frac{1}{s'(x)} |n(dx)| < \infty \quad (3.14)$$

for an arbitrary compact K contained in (l, r) . First note that

$$\int_K |h''(x)| \frac{1}{s'(x)} dx + \int_K \frac{1}{s'(x)} |n(dx)| < \infty$$

since h' is of finite variation and s' is continuous and strictly positive on (l, r) .

Moreover,

$$\int_K \left| \frac{2b(x)}{\sigma^2(x)} h'(x) \right| dx = C + \int_K \left(\int_c^y \left| \frac{2b(x)}{\sigma^2(x)} \right| dx \right) |dh'(y)|,$$

for some $C < \infty$ and $c \in K$ due to the finiteness of h' and $\int_c^y \left| \frac{2b(x)}{\sigma^2(x)} \right| dx$ at the boundary of K . However, the integral in the above representation is finite since dh'

is of finite variation and $\int_c^y \left| \frac{2b(x)}{\sigma^2(x)} \right| dx$ is bounded in K . This completes the proof that (3.14) holds for an arbitrary compact set K , which in turn yields the claim.

- (3) It follows from the previous part that $\Lambda(h)$ is of finite variation. Since $(h(X_s)_{s \leq t})$ is away from 0, path by path, for $t < \zeta$, it immediately follows that M is of finite variation, too.

Since h can be considered as a difference of convex functions, it follows from Ito-Tanaka formula that on $[t < \zeta]$

$$\begin{aligned} h(X_t) &= h(y) + \int_0^t h'(X_s) dX_s + \frac{1}{2} \int_l^r \tilde{L}_t^x \{h''(x) dx + n(dx)\} \\ &= \int_0^t h'(X_s) dX_s + \frac{1}{2} \int_0^t \sigma^2(X_s) h''(X_s) ds + \int_l^r L^x \frac{1}{s'(x)} n(dx). \end{aligned}$$

Thus, a simple application of integration by parts formula yields

$$h(X_t)M_t = h(y) + \int_0^t h'(X_s)M_s \sigma(X_s) dB_s, \quad t < \zeta,$$

proving the local martingale property for $h(X)M$. In particular, $h(X)M$ is a continuous non-negative supermartingale with an integrable limit as $t \rightarrow \zeta$.

Finally, due to the hypotheses on r_s it follows from Theorem 5.5.15 in [9] that there exists a unique weak solution to (3.11).

- (4) Since $h(X)^{ST}M^T$ is a uniformly integrable martingale under P^y , we deduce from Girsanov's theorem and the uniqueness in law of the solutions of (3.11) that

$$R^{h,y}(\Gamma) = \frac{1}{h(y)} E^y [\mathbf{1}_\Gamma h(X_T)M_T].$$

□

Example 3.1. Suppose $\delta > 2$ and consider a δ -dimensional Bessel process on $(0, \infty)$, i.e. a one-dimensional diffusion with the dynamics

$$dX_t = 2\sqrt{X_t}dB_t + \delta dt.$$

The scale function is given by $s(x) = 1 - x^{\frac{2-\delta}{2}}$. Thus, X is transient and approaches to ∞ as $t \rightarrow \infty$, while 0 is an inaccessible boundary.

Let $h(x) := x^{\frac{2-\delta}{4}}$ and define

$$M_t := \exp \left(\frac{(\delta-2)^2}{8} \int_0^t \frac{1}{X_s} ds \right), \quad t \geq 0.$$

Then, it follows from Theorem 3.1 that M is of finite variation and $h(X)M$ is a local martingale. Moreover,

$$r_s(x) = \frac{\delta-2}{2} \int_1^x \frac{1}{u} du = \log x, \quad x > 0.$$

Thus, $-r_s(0) = r_s(\infty) = \infty$, and we conclude that (h, M) is a recurrent transform by invoking Theorem 3.1 again. The transformation yields the following SDE for the resulting

process

$$dX_t = 2\sqrt{X_t}dB_t + 2dt,$$

which is the SDE for a 2-dimensional squared Bessel process. Recall (or see p.442 of [18]) that 0 is polar for a 2-dimensional squared Bessel process.

The following proposition gives another example of a recurrent transform, which will let us achieve the first step of our desired conditioning.

Proposition 3.1. *Consider the pair (h, M) defined by*

$$h(x) := u(x, y), \quad x \in (l, r), \quad \text{and} \quad M_t = \exp\left(\frac{L_t^y}{u(y, y)}\right).$$

Then, the following hold:

- (1) (h, M) is a recurrent transform for X .
- (2) There exists a unique weak solution to

$$X_t = y + \int_0^t \sigma(X_s)dB_s + \int_0^t \left\{ b(X_s) + \sigma^2(X_s) \frac{u_x(X_s, y)}{u(X_s, y)} \right\} ds, \quad t \geq 0, \quad (3.15)$$

where u_x denotes the first partial left derivative of $u(x, y)$ with respect to x .

- (3) Moreover, if $R^{h,y}$ denotes the law of the solution, then, for all $a > 0$, we have⁴ $R^{h,y}(L_\infty^y \geq a) = R^{h,y}(\tau_{a-}^y < \infty) = 1$ and

$$\frac{dR^{h,y}}{dP^y} \Big|_{\mathcal{F}_{\tau_{a-}^y}} = \exp\left(\frac{a}{u(y, y)}\right) \mathbf{1}_{[\tau_{a-}^y < \zeta]}. \quad (3.16)$$

Proof. (1) It follows from (2.7)-(2.9) that $x \mapsto u(x, y)$ is absolutely continuous and its left derivative is of finite variation. In particular,

$$n(dx) = -s'(y)\varepsilon_y,$$

where ε_y is the dirac measure at point y . This further implies $\Lambda_t(h) = -L_t^y$. Since Ah vanishes, Theorem 3.1 suggests we define

$$M_t = \exp\left(\int_0^t \frac{1}{u(X_s, y)} dL_s^y\right) = \exp\left(\frac{1}{u(y, y)} L_t^y\right),$$

where the last equality is due to the fact that the support of dL^y is carried by the set $\{t : X_t = y\}$.

Next, consider the function

$$r_s(x) = \int_y^x \frac{s'(z)}{u^2(z, y)} dz,$$

and suppose, first, that $s(l) = 1 - s(r) = 0$. Then, for $x < y$,

$$r_s(x) = \frac{1}{(1 - s(y))^2} \int_y^x \frac{s'(z)}{s^2(z)} dz = \frac{1}{(1 - s(y))^2} \left(\frac{1}{s(y)} - \frac{1}{s(x)} \right),$$

⁴Recall Remark 1 for the interpretation of τ_{a-}^y under $R^{h,y}$.

which in particular shows that $\lim_{x \rightarrow l} r_s(x) = -\infty$. Similarly, for $x > y$,

$$r_s(x) = \frac{1}{s^2(y)} \int_y^x \frac{s'(z)}{(1-s(z))^2} dz = \frac{1}{s^2(y)} \left(\frac{1}{1-s(x)} - \frac{1}{1-s(y)} \right),$$

and, thus, $s_r(\infty) = \infty$. The other cases are handled the same way to show $-r_s(l) = r_s(r) = \infty$. This completes the proof of that (h, M) is a recurrent transform via Theorem 3.1.

- (2) This follows from the previous part and the definition of a recurrent transformation.
- (3) Observe that $h(X_{\tau_{a-}^y})M^{\tau_{a-}^y}$ is a bounded martingale. Thus, it follows from (3.13) that

$$\begin{aligned} R^{h,y}(\tau_{a-}^y < \infty) &= \frac{1}{u(y,y)} E^y \left[\mathbf{1}_{[\tau_{a-}^y < \infty]} u(X_{\tau_{a-}^y}, y) \exp \left(\frac{L_{\tau_{a-}^y}^y}{u(y,y)} \right) \right] \\ &= \exp \left(\frac{a}{u(y,y)} \right) P^y(\tau_{a-}^y < \zeta), \end{aligned}$$

where the last equality is due to the fact that $X_{\tau_{a-}^y} = y$ and $L_{\tau_{a-}^y}^y = a$ by the continuity of X and of L^y . On the other hand,

$$P^y(\tau_{a-}^y < \zeta) = P^y(L_\infty^y \geq a) = \exp \left(-\frac{a}{u(y,y)} \right)$$

in view of (2.5). This shows that $R^{h,y}(\tau_{a-}^y < \infty) = R^{h,y}(L_\infty^y \geq a) = 1$. Applying (3.13) once more yields the desired absolute continuity on $\mathcal{F}_{\tau_{a-}^y}$. □

Remark 3. *It is trivial to check that (h, M) -recurrent transform of X has $h^2 dm$ as its speed measure. In the specific case considered in the above proposition the recurrent transform is a one-dimensional diffusion with scale*

$$r_s(x) = \int_c^x \frac{s'(z)}{u^2(z,y)} dz$$

and the speed measure $u^2(z,y)m(dz)$. Note that this is not the only diffusion with this scale function and the speed measure. Indeed, if one considers the h -transform of X via $h(x) = u(x,y)$, one obtains a diffusion which amounts to conditioning the paths of X to converge to y and killed at its last exit from y . The resulting diffusion is obviously a transient diffusion but has the same scale and the speed (see, e.g. Theorem 6.2 in [7] or Paragraph 31 in [2]). The crucial difference between the two transformations is that one involves killing. More precisely, the h -transform has a killing measure

$$k^h(dz) = u(y,y)\varepsilon_y,$$

where ε_y is the point mass at y (see, again, Theorem 6.2 in [7] or Paragraph 31 in [2]), while the killing measure for the recurrent transform is null.

Killing of the trajectories in the h -transform is also apparent from the following relationship between the measures:

$$E^{h,x}[F] = \frac{E^x[Fu(X_t, y)]}{u(x, y)} = E^x[F\mathbf{1}_{[G_y > t]}].$$

In the above F is an \mathcal{F}_t -measurable random variable, $G_y = \sup\{t : X_t = y\}$, and $E^{h,x}$ is the expectation operator with respect to the law of the h -transform (see Section 3.9 in [11] for more details) started at x . The above identity in particular implies

$$P^{h,x}(\zeta > t) = P^x(G^y > t), \quad \forall t \geq 0,$$

i.e., $P^{h,x}$ -distribution of ζ coincides with the law of G^y under P^x .

Given this close relationship between the recurrent transform and the h -transform one may wonder whether it is possible to obtain the latter from the former via a killing. This is in fact possible. All we have to do is to kill R at some random time with distribution equalling to that of G^y and at which R equals y .

To this end let τ_a^y be the right continuous inverse of the diffusion local time of R at level y . Then,

$$\begin{aligned} R^{h,x} \exp(-\lambda \tau_a^y) &= \exp\left(-\frac{a}{u_R^\lambda(y, y)}\right) R^{h,x} \exp(-\lambda T_y) \\ &= \exp\left(-\frac{a}{u_R^\lambda(y, y)}\right) u(y, y) E^x \exp(-\lambda T_y), \end{aligned}$$

where u_R^λ is the λ -potential kernel for R with respect to $u^2(z, y)m(dz)$ given by

$$u_R^\lambda(z, y) = \frac{u^\lambda(z, y)}{u(z, y)u(y, y)}$$

and u^λ is the λ -potential kernel for X with respect to m . The first equality in above follows from the strong Markov property of R and p.22 of [2], while the second is a consequence of (3.13). Moreover, (see Theorem 3.6.5 in [11])

$$E^x \exp(-\lambda T_y) = \frac{u^\lambda(x, y)}{u^\lambda(y, y)}$$

implying

$$R^{h,x} \exp(-\lambda \tau_a^y) = \exp\left(-\frac{au^2(y, y)}{u_\lambda(y, y)}\right) \frac{u^\lambda(x, y)u(y, y)}{u^\lambda(y, y)}. \quad (3.17)$$

On the other hand, expression (54) in [17] gives

$$E^x \exp(-\lambda G^y) = \frac{u^\lambda(x, y)}{u(y, y)}. \quad (3.18)$$

Thus, if α is an independent “random variable” with a uniform distribution over $(0, \infty)$, it follows from (3.17) that τ_α^y has the Laplace transform given by

$$\frac{u^\lambda(x, y)u(y, y)}{u^\lambda(y, y)} \int_0^\infty \exp\left(-\frac{au^2(y, y)}{u_\lambda(y, y)}\right) da = \frac{u^\lambda(x, y)}{u(y, y)},$$

which coincides with (3.18). Moreover, $R_{\tau_\alpha^y} = y$. Thus, the h -transform of X with the minimal excessive function $h(x) = u(x, y)$ can be obtained by killing the $(u(\cdot, y), M)$ -recurrent transform of X at τ_α^y .

Remark 4. The procedure at the end of the previous remark gives us a way to simulate the last passage time of a transient diffusion as a mixture of first hitting times of a related diffusion, which might prove to be useful for numerical studies especially when the potential kernels are not known explicitly.

Proposition 3.1 tells us what to do in our first step: We run the (h, M) -recurrent transformation given in the proposition until τ_{a-}^y , which is finite with probability 1. That is,

$$X_{t \wedge \tau_{a-}^y} = y + \int_0^{t \wedge \tau_{a-}^y} \sigma(X_s) dB_s + \int_0^{t \wedge \tau_{a-}^y} \left\{ b(X_s) + \sigma^2(X_s) \frac{u_x(X_s, y)}{u(X_s, y)} \right\} ds.$$

Recall that $[\tau_{a-}^y < \infty] = [L_\infty^y \geq a]$. Thus, the above makes sure that the conditioned process will have its local time at y being at least equal to a in the limit. It now remains to make sure that the process never visits y after τ_{a-}^y .

4. BESSEL-TYPE MOTIONS AND STEP 2

Recall that the second step of our recipe is to keep X away from y after τ_{a-}^y . As one can guess this can be achieved by conditioning X never hit y using an h -transform. The next proposition make this idea rigorous and gives us the candidate drifts that ensure X has the prescribed limit while avoiding y at the same time.

Proposition 4.1. *Let X be a regular diffusion satisfying Assumption 2.1.*

- (1) *Suppose $s(l) = 0$. There exists a regular diffusion on (l, y) with the scale function s_l and the speed measure, m_l , defined by*

$$s_l(x) := \frac{1}{s(y) - s(x)}, \quad m_l(dx) := (s(y) - s(x))^2 m(dx).$$

y is an entrance boundary for this diffusion, which is also the unique weak solution to

$$R_t = x + \int_0^t \sigma(R_s) dB_s + \int_0^t \left\{ b(R_s) - \frac{s'(R_s) \sigma^2(R_s)}{s(y) - s(R_s)} \right\} ds, \quad t < \zeta, \quad (4.19)$$

where $x \in (l, y]$ and $\zeta = \inf\{t \geq 0 : R_{t-} = l\}$. Moreover, $\lim_{t \rightarrow \infty} R_t = l$, $Q^{x,0}$ -a.s., where $Q^{x,0}$ is the law of the weak solution to the SDE above.

- (2) *Suppose $s(r) = 1$. There exists a regular diffusion on (y, r) with the scale function s_r and the speed measure, m_r , defined by*

$$s_r(x) := \frac{1}{s(y) - s(x)}, \quad m_r(dx) := (s(y) - s(x))^2 m(dx).$$

y is an entrance boundary for this diffusion, which is also the unique weak solution to

$$R_t = x + \int_0^t \sigma(R_s) dB_s + \int_0^t \left\{ b(R_s) + \frac{s'(R_s) \sigma^2(R_s)}{s(R_s) - s(y)} \right\} ds, \quad t < \zeta, \quad (4.20)$$

where $x \in [y, r)$ and $\zeta = \inf\{t \geq 0 : R_{t-} = r\}$. Moreover, $\lim_{t \rightarrow \infty} R_t = r$, $Q^{x,1}$ -a.s., where $Q^{x,1}$ is the law of the weak solution to the SDE above.

Proof. We will only prove the proposition in case (1), the proof of the second part follows identical steps.

Clearly, s_l is strictly increasing and continuous since $s' > 0$ on (l, y) . Moreover, it can be directly checked that $0 < m_l((a, z)) < \infty$ for $l < a < z < y$ using the analogous property for m and the fact that s is strictly increasing. Thus, we can associate a regular diffusion to (s_l, m_l) . To see that y is an entrance boundary, observe that for $l < z < y$

$$\int_z^y (s_l(a) - s_l(z))(s(y) - s(a))^2 m(da) < \infty.$$

Indeed, since $s_l(y-) = \infty$,

$$\lim_{a \rightarrow y} \frac{s_l(a) - s_l(z)}{(s(y) - s(a))^{-2}} = \frac{1}{2} \lim_{a \rightarrow y} \frac{\frac{s'(a)}{(s(y) - s(a))^2}}{s'(a)(s(y) - s(a))^{-3}} = 0,$$

implying the finiteness of the above integral near y due to the fact that y belongs to the interior of the state space of the regular diffusion with scale s and speed m . Finiteness of the integral near z follows from the boundedness of s_l and s on the compact subsets of (l, y) and the finiteness of m in the interior of (l, r) .

In order to conclude y is an entrance boundary, we also need to verify that

$$\int_z^y m_l((z, a)) \frac{s'(a)}{(s(y) - s(a))^2} da = \infty.$$

The above integral, indeed, diverges since $m_l((z, y)) > 0$, and

$$\int_{z'}^y \frac{s'(a)}{(s(y) - s(a))^2} da = \infty$$

for any z' such that $z < z' < y$.

In order to show the weak existence and uniqueness of solutions to (4.19) with $x \in (l, y)$, we will again make use of the Engelbert-Schmidt criteria analogous to (2.1). Observe that in view of our assumption on σ and b , all that we need to check is the local integrability of $\frac{s'}{s(y) - s}$.

Indeed, for any (x, z) such that $l < x < z < y$

$$\int_x^z \frac{s'(u)}{s(y) - s(u)} du = \log \frac{s(y) - s(z)}{s(y) - s(x)} < \infty.$$

The existence and uniqueness of a weak solution when the starting point is y , i.e. the entrance boundary, follows from Theorem 2.1.

Finally, the limit as $t \rightarrow \infty$ follows from the fact that $s_l(l) < \infty$ while $s_l(y) = \infty$ (see Proposition 5.5.22 in [9]). \square

We will next prove a result which shows that the processes obtained above can be considered as the analogues of 3-dimensional Bessel process, which is the killed Brownian motion on $(0, \infty)$ conditioned to converge to ∞ . As such, they define the entrance laws for the excursions of the original process, X , away from y as shown by Pitman and Yor (see Section 3

of [16]) and can be considered as an excursion of X away from y conditioned to last forever. Moreover, a time reversal relationship exists between the solutions of (4.19) and those of (2.3) stopped at y akin to the one between the 3-dimensional Bessel process and the killed Brownian motion established by Williams [20]. This relationship will be proved by a time reversal result of Nagasawa [14]. The following version of this result is taken from Sharpe [19].

Theorem 4.1 (Nagasawa [14]). *Let X and \hat{X} be standard Markov processes in duality on their common state space with respect to a σ -finite measure, ξ . Let $u(x, y)$ denote the potential kernel density with respect to ξ so that for any positive and measurable f*

$$E^x \int_0^\infty f(X_t) dt = \int u(x, z) f(z) \xi(dz).$$

Let G be a co-optional time and define

$$\tilde{X}_t = \begin{cases} X_{(G-t)-}, & \text{on } [G < \infty] \text{ if } 0 < t < G; \\ \Delta, & \text{otherwise.} \end{cases}$$

Fix an initial law λ and let $v(x) = \int u(x, z) \lambda(dz)$. Then, under P^λ , the process \tilde{X} is a homogeneous Markov process with transition semigroup, (\tilde{P}_t) defined by

$$\tilde{P}_t f(x) = \begin{cases} \frac{P_t f v(x)}{v(x)}, & \text{if } 0 < v(x) < \infty; \\ 0, & \text{otherwise.} \end{cases}$$

Now, we can state and prove the results announced in the paragraph preceding the above theorem.

Proposition 4.2. *Let X be a regular diffusion satisfying Assumption 2.1, $y \in (l, r)$, and denote by X^0 (resp. X^1) the killed diffusion process on (l, y) (resp. (y, r)) with the scale function s and the speed measure m .⁵*

- (1) *Suppose $s(l) = 0$ (resp. $s(r) = 1$). Then, for any bounded and measurable f and $x \neq y$*

$$Q_t^0 f(x) = \frac{P_t^0 f(s(y) - s)(x)}{s(y) - s(x)} \left(\text{resp. } Q_t^1 f(x) = \frac{P_t^1 f(s - s(y))(x)}{s(x) - s(y)} \right),$$

where $(Q_t^0)_{t \geq 0}$ (resp. $(Q_t^1)_{t \geq 0}$) is the semigroup associated to the solutions of (4.19) (resp. (4.20)) while $(P_t^0)_{t \geq 0}$ (resp. $(P_t^1)_{t \geq 0}$) is the transition semigroup of X^0 (resp. X^1).

- (2) *Let R be the solution of (4.19) (resp. (4.20)) with $x = y$. Pick a $z \in (l, y)$ (resp. $z \in (y, r)$) and define the last passage time*

$$G_z := \sup\{t : R_t = z\}.$$

Next, let Y be the diffusion on (l, y) (resp. (y, r)) obtained by conditioning X^0 (resp. X^1) converge to y with $Y_0 = z$. Then, the processes

$$\{R_{G_z-t}, 0 < t < G_y\} \text{ and } \{Y_t, 0 < t < S_y\}$$

⁵These are simply the solutions of (2.3) killed when they reach y or one of l and r

have the same law, where

$$S_y = \inf\{t : Y_t = y\}.$$

In particular, G_z and S_y are finite and have the same distribution.

Proof. We will only prove the above result when $s(l) = 0$. The other case is handled in the same way.

- (1) Suppose $x < y$ and consider the martingale $(s(y) - s(X_{t \wedge T_y}))$, where X is a solution of (2.3) with $X_0 = x$, and T_y is the first passage time of y by X . Then, Girsanov's theorem in conjunction with the weak uniqueness of solutions of (4.19) yields

$$Q_t^0 f(x) = \frac{E^x [f(X_t) (s(y) - s(X_{t \wedge T_y}))]}{s(y) - s(x)} = \frac{E^x [f(X_t) (s(y) - s(X_t)) \mathbf{1}_{[t < T_y])}]}{s(y) - s(x)},$$

which establishes the identity for $x < y$.

- (2) Since (Q_t^0) is the semigroup of R , it is self-dual with respect to m_l . Its potential kernel with respect to m_l is symmetric and is given by

$$u_l(x, z) = s_l(x) - s_l(l) = \frac{s(x)}{s(y)(s(y) - s(x))}, \quad x \leq z,$$

since $s_l(y) = \infty$ (see the beginning of p.20 in [2]). Next, define

$$v(x) := \int_l^x u_l(x, z) \varepsilon_y(dz) = u_l(x, y) = \frac{s(x)}{s(y)(s(y) - s(x))},$$

where ε_y is the point mass at y . Since G_z is a $Q^{y,0}$ -a.s. finite co-optional time, Theorem 4.1 yields that, under $Q^{y,0}$, the transition semigroup of the time-reversed process, $(R_{G_z-t})_{0 < t < G_z}$, is given by

$$\tilde{P}_t f(x) = \frac{Q_t^0 f v(x)}{v(x)}.$$

On the other hand, it follows from part (1) that

$$\frac{Q_t^0 f v(x)}{v(x)} = \frac{P_t^0 f v(s(y) - s)(x)}{v(x)(s(y) - s(x))} = \frac{P_t^0 f s(x)}{s(x)},$$

which establishes the claims. □

In view of the above proposition and following the footsteps of McKean [12], any solution of (4.19) (resp. (4.20)) will be called a *Bessel-type motion* with law $Q^{x,0}$ (resp. $Q^{x,1}$).

5. MAIN RESULTS AND THEIR PROOFS

We are now ready to prove our main results. In what follows the inverse local time should be interpreted in terms of the semimartingale local time as explained in Remark 1.

Theorem 5.1. *There exists a filtered probability space, $(\Omega, \mathcal{G}, (\mathcal{G}_t)_{t \geq 0}, P^{L,a})$, which contains a Bernoulli random variable, θ , with⁶ $P^{L,a}(\theta = 1) = \rho(y) = 1 - P^{L,a}(\theta = 0)$ and the adapted pair (X, B) such that $(\mathcal{G}_t)_{t \geq 0}$ is right-continuous, B is a standard Brownian motion independent of θ , and X satisfies*

$$\begin{aligned} X_t = & y + \int_0^t \sigma(X_s) dB_s + \int_0^t b(X_s) ds + \int_0^{t \wedge \tau_{a-}^y} \sigma^2(X_s) \frac{u_x(X_s, y)}{u(X_s, y)} ds \\ & + \int_{t \wedge \tau_{a-}^y}^t \sigma^2(X_s) \left\{ \theta \mathbf{1}_{[X_s > y]} \frac{s'(X_s)}{s(X_s) - s(y)} - (1 - \theta) \mathbf{1}_{[X_s < y]} \frac{s'(X_s)}{s(y) - s(X_s)} \right\} ds, \quad t < \zeta. \end{aligned} \quad (5.21)$$

Moreover, weak uniqueness holds for the solutions of the above SDE. The law induced by its solutions, denoted by $P^{L,a}$ with a slight abuse of notation, on $C(\mathbb{R}_+, I)$ satisfies the following properties:

- (1) The mapping $a \mapsto P^{L,a}(E)$ is measurable for any Borel subset, E , of $C(\mathbb{R}_+, I)$ endowed with the locally uniform topology.
- (2) There exists a filtered probability space, $(\tilde{\Omega}, \tilde{\mathcal{G}}, (\tilde{\mathcal{G}}_t)_{t \geq 0}, P^{L,g})$, which contains a Bernoulli random variable, θ , with $P^{L,g}(\theta = 1) = \rho(y) = 1 - P^{L,g}(\theta = 0)$, another \mathbb{R}_{++} -valued random variable Γ with distribution g , and the adapted pair (X, B) such that i) $(\tilde{\mathcal{G}}_t)_{t \geq 0}$ is right-continuous; ii) B is a standard Brownian motion; iii) B , θ and Γ are mutually independent; and iv) X solves

$$\begin{aligned} X_t = & y + \int_0^t \sigma(X_s) dB_s + \int_0^t b(X_s) ds + \int_0^{t \wedge \tau_{\Gamma-}^y} \sigma^2(X_s) \frac{u_x(X_s, y)}{u(X_s, y)} ds \\ & + \int_{t \wedge \tau_{\Gamma-}^y}^t \sigma^2(X_s) \left\{ \theta \mathbf{1}_{[X_s > y]} \frac{s'(X_s)}{s(X_s) - s(y)} - (1 - \theta) \mathbf{1}_{[X_s < y]} \frac{s'(X_s)}{s(y) - s(X_s)} \right\} ds, \quad t < \zeta. \end{aligned} \quad (5.22)$$

Similarly, the uniqueness in law holds for the solutions of the above SDE with properties i)-iv). Furthermore, denoting the law of its solutions by $P^{L,g}$, we have the following disintegration formula:

$$P^{L,g} = \int_0^\infty g(da) P^{L,a}. \quad (5.23)$$

- (3) $P^{L,a}(L_\infty^y = a) = P^{L,g}(L_\infty^y = \Gamma) = 1$.

Proof. A weak solution can be constructed by the time-change method of Engelbert-Schmidt first applied to a Brownian motion until τ_{a-}^y and then to a 3-dimensional Bessel process. The uniqueness in law can be shown by the same argument employed in the proof of Theorem 2.1. The claim on the existence and the uniqueness of the SDE is basically a combination of Propositions 3.1 and 4.1.

- (1) Note that it suffices to show

$$a \mapsto P^{L,a}(X_{t_i} \in E_i; i = 1, \dots, n)$$

is measurable for any n , where $0 < t_1 < \dots < t_n$ are arbitrary positive real numbers and E_i is an interval contained in I .

⁶See (2.10) for the definition of ρ .

Let $J := \min\{i : t_i \geq \tau_{a-}^y\}$ and observe that J depends on a in a measurable way since $a \mapsto \tau_{a-}^y$ is measurable due to the monotonicity of τ_a^y in a . Then,

$$P^{L,a}(X_{t_i} \in E_i; i = 1, \dots, n) = E^{h,y} \left[\mathbf{1}_{[X_{t_1} \in E_1]} \dots \mathbf{1}_{[X_{t_{J-1}} \in E_{J-1}]} \pi(\tau_{a-}^y, J, \theta) \right],$$

where $E^{h,y}$ is expectation with respect to $R^{h,y}$, which is the law of the solutions of (3.15), and

$$\pi(t, j, \theta) = Q^{y,\theta}(X_{(t_j-t)^+} \in E_j, X_{(t_{j+1}-t)^+} \in E_{j+1}, \dots, X_{(t_n-t)^+} \in E_n),$$

with $Q^{y,\theta}$ being the law of (4.19) or (4.20) depending on the value of θ . Now, since θ is independent of B and $R^{h,y}$ is absolutely continuous with respect to P^y with

$$\frac{dR^{h,y}}{dP^y} = \exp\left(\frac{a}{u(y,y)}\right) \mathbf{1}_{[\tau_{a-}^y < \zeta]},$$

as given by Proposition 3.1, the claim follows.

- (2) Existence follows from constructing the solution on the product space $C(\mathbb{R}_+, I) \times \mathbb{R}_+$. We can construct the probability space on $\Omega \times \mathbb{R}_+$ by considering the product σ -algebras generated by the measurable rectangles and the product measure, P^L , obtained as the product of $P^{L,a}$ and g , which in particular obeys the disintegration formula. This probability space is then endowed with the natural filtration of the co-ordinate process augmented with the universal null-sets to yield a right-continuous filtration. This ensures the existence of a solution with the given properties. Uniqueness in law follows from the same time-change method of Engelbert-Schmidt applied, e.g. in Theorem 2.1, previously.
- (3) This follows from the construction since $L_{\tau_{a-}^y}^y = a$ and R does not visit y after τ_{a-}^y .

□

The following corollary establishes the connection between the solutions of (5.21) and (5.22) and the Doob-Meyer decomposition of the solutions of (2.3) when the underlying filtration is enlarged with L_∞^y .

Corollary 5.1. *Let X be a regular diffusion satisfying Assumption 2.1 and $(\Omega, \mathcal{G}, (\mathcal{G}_t)_{t \geq 0}, P)$ be a filtered probability space in which it solves (2.3) with $X_0 = y$. Consider the filtration $(\mathcal{H}_t)_{t \geq 0}$, where $\mathcal{H}_t = \mathcal{G}_t \vee \sigma(L_\infty^y)$. Then,*

$$\begin{aligned} X_t &= y + \int_0^t \sigma(X_s) d\beta_s + \int_0^t b(X_s) ds + \int_0^{t \wedge \tau_{\Gamma-}^y} \sigma^2(X_s) \frac{u_x(X_s, y)}{u(X_s, y)} ds \\ &\quad + \int_{t \wedge \tau_{\Gamma-}^y}^t \sigma^2(X_s) \frac{s'(X_s)}{s(X_s) - s(y)} ds, \quad t < \zeta, \end{aligned} \tag{5.24}$$

where $\Gamma := L_\infty^y$ and β is an $(\mathcal{H}_t)_{t \geq 0}$ -Brownian motion stopped at ζ .

In particular, X is a weak solution of (5.22), where $\Gamma = L_\infty^y$, $g(da) = \frac{1}{u(y,y)} \exp\left(-\frac{a}{u(y,y)}\right) da$, and $\theta = \mathbf{1}_{[R_\infty=r]}$.

Proof. Directly following the arguments in the proof of Theorem 1.6 in [10] and keeping in mind that the \mathcal{G}_t -conditional distribution of L_∞^y has an atom (as in the case of Example 1.7 in [10]), we deduce that

$$M_t := X_t - y - \int_0^t b(X_s) ds - \int_0^{t \wedge \tau_{\Gamma-}^y} \sigma^2(X_s) \frac{u_x(X_s, y)}{u(X_s, y)} ds - \int_{t \wedge \tau_{\Gamma-}^y}^t \sigma^2(X_s) \frac{s'(X_s)}{s(X_s) - s(y)} ds$$

is an $(\mathcal{H}_t)_{t \geq 0}$ local martingale stopped at ζ . Note that the above is well-defined since, the integrand of the last integral has a constant sign and P -a.s.

$$\int_0^t \{ \sigma^2(X_s) + |b(X_s)| \} ds < \infty, \text{ on } [t < \zeta],$$

by the definition of weak solutions. Therefore, on $[t < \zeta]$, we have

$$\int_0^{t \wedge \tau_{\Gamma-}^y} \sigma^2(X_s) \left| \frac{u_x(X_s, y)}{u(X_s, y)} \right| ds < \infty$$

due to the continuity (and therefore boundedness) of $\frac{u_x(X, y)}{u(X, y)}$ on compact subintervals of $[0, \zeta]$.

It can also be directly verified that $[M, M]_t = \int_0^t \sigma^2(X_s) ds$ on $[t < \zeta]$. Thus, since $\sigma(x) > 0$ for $x \in (l, r)$ by assumption, we may define

$$\beta_t := \int_0^{t \wedge \zeta} \frac{1}{\sigma(X_s)} dM_s.$$

Observe that the above stochastic integral is well-defined since M is a continuous local martingale and on $[t < \zeta]$

$$\int_0^t \frac{1}{\sigma^2(X_s)} d[M, M]_s = t.$$

By Lévy's characterisation we easily deduce that β is an $(\mathcal{H}_t)_{t \geq 0}$ -Brownian motion stopped at ζ , which in turn yields that X satisfies (5.24). Moreover, β is independent of L_∞^y .

To show that X is the weak solution of (5.22) with the given set of Γ, g , and θ , recall from (2.5) that the P -distribution of L_∞^y is exponential with parameter $\frac{1}{u(y, y)}$ and observe that the dynamics of X in (5.24) is the same as those given by (5.22) once we replace B with β and notice that $[\theta = 1] = [X_{t+\tau_{\Gamma-}^y} > y]$ for all $t > 0$. Moreover, $P(\theta = 1) = \rho(y)$ is trivially satisfied due to the definition of ρ . Thus, it remains to show that θ, β and L_∞^y are independent from each other.

We have already observed that β and L_∞^y are independent. The independence of L_∞^y and X_∞ under P is obvious when only one of $s(l)$ and $s(r)$ is finite. If both of them are finite, the result follows from Proposition 2.1.

Note that (L_t^y, X_t) is strong Markov with respect to $(\mathcal{H}_t)_{t \geq 0}$ given L_∞^y . Thus, given $X_{\tau_{\Gamma-}^y}$ and $L_{\tau_{\Gamma-}^y}^y$, X_∞ is independent of $(\beta_{t \wedge \tau_{\Gamma-}^y})_{t \geq 0}$. However, $X_{\tau_{\Gamma-}^y} = y$ and $L_{\tau_{\Gamma-}^y}^y = \Gamma = L_\infty^y$. Since L_∞^y is independent of β , we deduce that X_∞ is independent of $(\beta_{t \wedge \tau_{\Gamma-}^y})_{t \geq 0}$, too. Moreover, $[X_\infty = r] = [X_t > y, \forall t > \tau_{\Gamma-}^y]$ implies $[X_\infty = r] \in \mathcal{H}_{\tau_{\Gamma-}^y}$ since $(\mathcal{H}_t)_{t \geq 0}$ is right-continuous. Therefore, X_∞ is independent of $(\beta_{t+\tau_{\Gamma-}^y} - \beta_{\tau_{\Gamma-}^y})_{t \geq 0}$, hence, of β .

□

Theorem 5.1 and Corollary 5.1 establish that the law of solutions of (5.21) is that of the solution of (2.3) conditioned on $[L_\infty^y = a]$ in view of the uniqueness in law of solutions of (5.22) and the disintegration formula (5.23) as stated below.

Corollary 5.2. *Let $P^{L,a}$ be the law on $C(\mathbb{R}_+, I)$ induced by solutions of (5.21) and consider the canonical space $(C(\mathbb{R}_+, I), \mathcal{B}, P^y)$, where \mathcal{B} is the Borel σ -algebra on $C(\mathbb{R}_+, I)$. Then, for all $t > 0$ and any bounded and measurable $F : C([0, t], I) \mapsto \mathbb{R}$ and $h : \mathbb{R} \mapsto \mathbb{R}$, the following holds:*

$$\int_0^\infty E^{L,a} [F(X_s; s \leq t)] h(a) \frac{1}{u(y, y)} \exp \left(-\frac{a}{u(y, y)} \right) da = E^y [F(X_s; s \leq t) h(L_\infty^y)]. \quad (5.25)$$

That is, $P^{L,a}$ is a regular conditional probability of \mathcal{B} given $L_\infty^y = a$.

Consequently, if X is a solution of (5.22) with $g(da) = \frac{1}{u(y, y)} \exp \left(-\frac{a}{u(y, y)} \right) da$, then, in its own filtration, it's a regular diffusion on (l, r) with scale function s and speed measure m .

Proof. Let X be a solution of (2.3) in some filtered probability space with a right-continuous filtration. As we have seen in Corollary 5.1, it follows (5.24) when the filtration is enlarged with L_∞^y . The same corollary also yields that X is a weak solution of (5.22) when $g(da) = \frac{1}{u(y, y)} \exp \left(-\frac{a}{u(y, y)} \right) da$. Since weak uniqueness holds for (5.22), we obtain (5.25) in view of (5.23).

The second claim follows from taking $h \equiv 1$ in (5.25), in which case the left-hand side of (5.25) equals

$$E^{L,g} [F(R_s; s \leq t)].$$

Thus, $P^{L,g} = P^y$, which implies the claim. \square

What is hidden, in fact, in the second part of the above corollary is a new path decomposition result for the original process X which can be restated, and upgraded to a theorem, as follows:

Theorem 5.2. *Let X be a weak solution of (2.3) with scale function s and potential kernel u . Pick a $y \in (l, r)$ and on a suitable probability space set up the following four independent elements:*

- (1) *An exponential random variable, Γ , with mean $u(y, y)$.*
- (2) *A Bernoulli random variable, θ , with $\mathbb{P}(\theta = 1) = \rho(y)$, where ρ is as in (2.10).*
- (3) *A process Y , which is a $(u(\cdot, y), M)$ recurrent transform of X run upto $\tau_{\Gamma-}^y$, where $M_t = \exp \left(\frac{L_t}{u(y, y)} \right)$.*
- (4) *A pair of Bessel-type motions, (R^0, R^1) with laws $(Q^{y,0}, Q^{y,1})$ and lifetimes (ζ^0, ζ^1) .*

Then, the process defined by

$$\tilde{X}_t := \begin{cases} Y_t, & t \leq \tau_{\Gamma-}^y \\ R_{t-\tau_{\Gamma-}^y}^\theta, & 0 < t - \tau_{\Gamma-}^y \leq \zeta^\theta, \end{cases}$$

has the same law as X .

Note that the random variable θ is needed only if $s(l) = 1 - s(r) = 0$. It must be emphasised that, in this case, the Bessel-type motions in the above setup are not independent from each other. In fact, the underlying Brownian motions in their SDE representations are the same. This is indeed possible since (4.19) and (4.20) have the same coefficients and differ only in their choice of the state space.

6. EXAMPLES

In this section we present some explicit examples that follow from Theorems 5.1 and 5.2. Our usual disclaimer regarding the interpretation of the inverse local time from Remark 1 applies.

6.1. Killed Brownian motion. Suppose X is a Brownian motion on $(-\infty, b)$ killed at $b > 0$. Thus, $s(x) = \frac{x}{b}$, $u(x, y) = 1 - s(x \vee y)$, and $X_\infty = b$, which is reached in finite time, a.s.. Taking $y = 0$ the equation (5.21) reads as

$$X_t = B_t - \int_0^{t \wedge \tau_{a-}^0} \frac{1}{b - X_s} \mathbf{1}_{[X_s > 0]} ds + \int_{t \wedge \tau_{a-}^0}^t \frac{1}{X_s} ds, \quad t < \zeta, \quad (6.26)$$

where ζ is the first hitting time of b , which occurs in finite time.

The first integral represents the recurrent transform, Y , stopped at τ_{a-}^0 , where

$$Y_t = B_t - \int_0^t \frac{1}{b - Y_s} \mathbf{1}_{[Y_s > 0]} ds.$$

If we let $U := b - Y$, then

$$U_t = b + \beta_t + \int_0^t \frac{1}{U_s} \mathbf{1}_{[U_s < b]} ds, \quad (6.27)$$

where $\beta = -B$. Although U resembles a 3-dimensional process, it clearly isn't since it is recurrent. It behaves like a Bessel process on the interval $(0, b)$, otherwise it moves like a Brownian motion, which makes it recurrent. This hints at the guess U being a recurrent transform of R , which turns out to be true.

Proposition 6.1. *Let U be as in (6.27). Then, it is an (h, M) -recurrent transform of the 3-dimensional Bessel process, R , which solves*

$$R_t = R_0 + B_t + \int_0^t \frac{1}{R_s} ds, \quad (6.28)$$

where

$$h(x) = \frac{1}{x \vee b}, \quad M_t = \exp(bL_t^b),$$

and L^b is the local time of R at b .

Proof. The potential kernel, u , for R is given by

$$u(x, y) = \frac{1}{x \vee y}.$$

Proposition 3.1 yields that $(u(\cdot, b), M)$ is a recurrent transform which results in the SDE

$$dX_t = dB_t + \left\{ \frac{1}{X_t} - \mathbf{1}_{[X_t > b]} \frac{1}{X_t} \right\} dt = dB_t + \mathbf{1}_{[X_t \leq b]} \frac{1}{X_t} dt.$$

Since $[X_t = b]$ is a null set, $\int_0^t \mathbf{1}_{[X_s = b]} ds = 0$, which in turn yields the claim. \square

Having characterised the recurrent transform and the Bessel process that led to (6.26), we can now state the path decomposition for the killed Brownian motion using Theorem 5.2.

Corollary 6.1. *On a suitable probability space set up the following three independent elements:*

- (1) *An exponential random variable, Γ , with mean 1.*
- (2) *A weak solution, U , of (6.27).*
- (3) *A 3-dimensional Bessel process, R , which solves (6.28) with $R_0 = 0$.*

Consider

$$\tilde{X}_t := \begin{cases} b - U_t, & t \leq \tau_{\Gamma-}^b \\ R_{t-\tau_{\Gamma-}^b}, & 0 < t - \tau_{\Gamma-}^b \leq S_b, \end{cases}$$

where $(\tau_t^b)_{t \geq 0}$ is the right-continuous inverse of the local time of U at level b and $S_b := \inf\{t \geq 0 : R_t = b\}$. Then, \tilde{X} has the same law as the Brownian motion starting at 0 and killed at b .

6.2. Ornstein-Uhlenbeck process. Consider the Ornstein-Uhlenbeck process

$$X_t = y + B_t + \int_0^t (rRX_s + b) ds \quad (6.29)$$

for some $r > 0$. Then, X is transient and has the scale function

$$s(x) = \sqrt{\frac{r}{\pi}} \int_{-\infty}^x \exp\left(-r\left(y - \frac{b}{r}\right)^2\right) dy, \quad (6.30)$$

with $s(-\infty) = 1 - s(\infty) = 0$. The equation (5.21) reads in this case as

$$\begin{aligned} X_t &= y + B_t + \int_0^t (rX_s + b) ds \\ &+ \int_0^{t \wedge \tau_{a-}^y} \left\{ \frac{s'(X_s)}{s(X_s)} \mathbf{1}_{[X_s \leq y]} - \frac{s'(X_s)}{1 - s(X_s)} \mathbf{1}_{[X_s > y]} \right\} ds \\ &+ \int_{t \wedge \tau_{a-}^y}^t \sigma^2(X_s) \left\{ \theta \mathbf{1}_{[X_s > y]} \frac{s'(X_s)}{s(X_s) - s(y)} - (1 - \theta) \mathbf{1}_{[X_s < y]} \frac{s'(X_s)}{s(y) - s(X_s)} \right\} ds, \end{aligned} \quad (6.31)$$

where θ is a random variable with $\rho(y) = s(y)$. We already know that there exists a weak solution, which is unique in law. The SDE above in fact possesses a unique strong solution. Indeed, since $\sigma \equiv 1$, Lemma IX.3.3, Corollary IX.3.4 and Proposition IX.3.2 in [18] imply that pathwise uniqueness holds for the SDEs (4.19) and (4.20) associated with the Ornstein-Uhlenbeck process above. Moreover, the auxiliary SDE

$$dX_t = d\beta_t + \left\{ \frac{s'(X_t)}{s(X_t)} \mathbf{1}_{[X_t \leq y]} - \frac{s'(X_t)}{1 - s(X_t)} \mathbf{1}_{[X_t > y]} \right\} dt$$

has pathwise uniqueness until the first exit time from any bounded interval by part i of Theorem IX.3.5 since the drift coefficient is bounded in compact subsets of \mathbb{R} . This establishes the pathwise uniqueness for the solutions of (3.15). Thus, in view of the celebrated result of Yamada and Watanabe (see Corollary 5.3.23 in [9]), there exists a unique strong solution to (3.15), hence, to (6.31).

6.3. Squared Bessel process. Now, X is a squared Bessel process on $(0, \infty)$ of order $\delta > 2$, i.e.

$$X_t = y + \int_0^t 2\sqrt{X_s} dB_s + \delta t.$$

Note that a scale function is given by $s(x) = 1 - x^{\frac{2-\delta}{2}}$. Thus, the equation (5.21) reads

$$\begin{aligned} X_t &= y + \int_0^t 2\sqrt{X_s} dB_s + \delta t \\ &\quad - 2(\delta - 2) \int_0^{t \wedge \tau_{a-}^y} \mathbf{1}_{[X_s > y]} ds + 2(\delta - 2) \int_{t \wedge \tau_{a-}^y}^t \frac{X_s^{\frac{2-\delta}{2}}}{y^{\frac{2-\delta}{2}} - X_s^{\frac{2-\delta}{2}}} ds. \end{aligned}$$

Observe that we do not need to introduce the random variable θ since $\rho(y) = 1$.

As in the previous example we can show that the solution is in fact the unique strong solution once we show that the following SDE has pathwise uniqueness:

$$X_t = y + \int_0^t 2\sqrt{X_s} dB_s + \delta t - 2(\delta - 2) \int_0^t \mathbf{1}_{[X_s > y]} ds.$$

Indeed, if R and X are two strong solutions then

$$\begin{aligned} |R_t - X_t| &= 2 \int_0^t \operatorname{sgn}(R_s - X_s)(\sqrt{R_s} - \sqrt{X_s}) dB_s \\ &\quad - 2(\delta - 2) \int_0^t \operatorname{sgn}(R_s - X_s)(\mathbf{1}_{[R_s > y]} - \mathbf{1}_{[X_s > y]}) ds + \tilde{L}_t \\ &\leq \int_0^t \operatorname{sgn}(R_s - X_s)(\sqrt{R_s} - \sqrt{X_s}) dB_s + \tilde{L}_t, \end{aligned}$$

where \tilde{L} is the *semimartingale* local time of $R - X$ at 0 and $\operatorname{sgn}(x) = 1$ if $x > 0$ and -1 , otherwise. If $\tau_x := \inf\{t \geq 0 : |R_t - X_t| > x\}$, then the stochastic integral stopped at τ_x is a true martingale since $|\sqrt{z} - \sqrt{z'}| < \sqrt{|z - z'|}$. Thus,

$$E|R_{t \wedge \tau_x} - X_{t \wedge \tau_x}| \leq E\tilde{L}_{t \wedge \tau_x}.$$

However, $\tilde{L} \equiv 0$ by Lemma IX.3.3 in [18] since, again, $|\sqrt{z} - \sqrt{z'}| < \sqrt{|z - z'|}$.

APPENDIX A. PROOF OF THEOREM 2.1

Proof of Theorem 2.1. Suppose that l is an entrance boundary and assume $l = 0$ without loss of generality. Since 0 is entrance, we must have $s(0) = -\infty$. Although $s(r) = 1$ by assumption, let's apply a further affine transformation and assume $s(r) = 0$. Also note that if r is a singular boundary, transience of X implies r is not entrance. Consider a 3-dimensional Bessel process, R , on $(0, \infty)$ starting at 0, i.e

$$R_t = B_t + \int_0^t \frac{1}{R_s} ds.$$

It is well-known that 0 is an entrance boundary for R (see [2] for a summary of results on Bessel processes), whose scale function is given by $p(x) := -\frac{1}{x}$. We will construct a weak

solution of (2.2) by change of time and scale applied to R following the ideas of Engelbert and Schmidt (see, e.g., Section 5.5 of [9]).

Observe that s is a C^1 -function whose derivative is absolutely continuous. It is clear that these properties are inherited by its inverse, s^{-1} . Since $s^{-1}(-\infty) = 0$, it follows from Ito's formula and the fact that

$$\frac{\sigma^2}{2}s'' + bs' = 0,$$

$Y = s^{-1}(p(R))$ is a semimartingale satisfying

$$Y_t = \int_0^t \frac{1}{R_u^2 s'(s^{-1}(p(R_u)))} dB_u + \int_0^t \frac{b(s^{-1}(p(R_u)))}{\sigma^2(s^{-1}(p(R_u))) [R_u^2 s'(s^{-1}(p(R_u)))]^2} du \quad (\text{A.32})$$

Consider the additive functional

$$A_t := \int_0^t \frac{1}{\sigma^2(s^{-1}(p(R_u))) [R_u^2 s'(s^{-1}(p(R_u)))]^2} du,$$

and its right-continuous inverse

$$T_t := \inf\{s \geq 0 : A_s > t\}.$$

We also define $A_\infty = \lim_{t \rightarrow \infty} A_t$ and $T_\infty = \lim_{t \rightarrow \infty} T_t$.

It follows from the occupation times formula that

$$A_t = 2 \int_0^\infty \frac{l_t^x}{x^2 \sigma^2(s^{-1}(p(x))) (s'(s^{-1}(p(x))))^2} dx = 2 \int_0^r \frac{l_t^{-\frac{1}{s(x)}}}{\sigma^2(x) s'(x)} dx,$$

where l^x is the diffusion local time for R . Since $R_t \rightarrow \infty$, a.s. and never visits 0 again, we immediately deduce that for every t , the mapping $x \mapsto l_t^x$ has a compact support, a.s., that is contained in $(0, \infty)$. Since it is also càdlàg, it is bounded. This implies that $A_t < \infty$, a.s., since for any $0 < z < u < r$

$$2 \int_z^u \frac{1}{\sigma^2(x) s'(x)} dx = m((z, u)) < \infty.$$

The same reasoning also yields that $A_{T_x} < \infty$, where $T_x = \inf\{t \geq 0 : R_t = x\}$ for some $x \in (0, \infty)$. Thus, the strong Markov property implies

$$Q^0(A_\infty < \infty) = Q^x(A_\infty < \infty),$$

where Q^x is the law of a 3-dimensional Bessel process starting at x . Mijatovic and Urusov show in Theorem 2.11 [13] that $Q^x(A_\infty < \infty) = 1$ (resp. $= 0$) if

$$\int_z^\infty \frac{1}{x^3 \sigma^2(s^{-1}(p(x))) (s'(s^{-1}(p(x))))^2} dx < \infty \text{ (resp. } = \infty)$$

for some z . After a change of variable the above integral turns into

$$- \int_{s^{-1}(p(z))}^r \frac{s(x)}{\sigma^2(x) s'(x)} dx,$$

which is finite if r is a regular boundary. Consequently, $A_\infty < \infty$, a.s. when r is regular.

If r is a singular boundary, we have already observed at the beginning of the proof that it is not entrance. If it is exit, the above integral will be finite, too. Indeed, that r is exit implies

$$\int_z^r m((z, x))s'(x)dx < \infty.$$

Also, note that $\lim_{x \rightarrow r} s(x)m((z, x))$ exists and equals

$$-\int_z^r \frac{s(x)}{\sigma^2(x)s'(x)}dx - \int_z^r m((z, x))s'(x)dx$$

under the assumption that r is an exit boundary. On the other hand, since $s(r) = 0$ and

$$\int_z^r \frac{s'(x)}{s(x)}dx = \log s(z) - \log s(r) = \infty,$$

we deduce that $\lim_{x \rightarrow r} s(x)m((z, x)) = 0$ since

$$\infty > \int_z^r m((z, x))s'(x)dx = \int_z^r s(x)m((z, x))\frac{s'(x)}{s(x)}dx.$$

Therefore, for any $z \in (0, r)$

$$-\int_z^r \frac{s(x)}{\sigma^2(x)s'(x)}dx = \int_z^r m((z, x))s'(x)dx < \infty,$$

and A_∞ is finite.

If r is a natural boundary, let r_n be a sequence of numbers in (l, r) increasing to r and observe that

$$\begin{aligned} -\int_z^r \frac{s(x)}{\sigma^2(x)s'(x)}dx &= \lim_{n \rightarrow \infty} \left\{ -s(r_n)m((z, r_n)) + \int_z^{r_n} m((z, x))s'(x)dx \right\} \\ &\geq \lim_{n \rightarrow \infty} \int_z^{r_n} m((z, x))s'(x)dx = \infty. \end{aligned}$$

Thus, $A_\infty = \infty$, a.s., when r is a natural boundary.

The behaviour of A near infinity affects the finiteness of T . If $A_\infty < \infty$, then $T_t = \infty$ on $[t \geq A_\infty]$. Otherwise, $T_t < \infty$, for every t . Moreover, it is easy to see that A is continuous and strictly increasing while T is continuous everywhere and strictly increasing on $[0, A_\infty]$. Moreover, $t = A_{T_t}$ for $t \leq A_\infty$ and $t = T_{A_t}$ for every $t < \infty$.

With the above characterisation of A and T , let us next consider $X_t := Y_{T_t}$ and $\mathcal{G}_t = \mathcal{F}_{T_t}$, where (\mathcal{F}_t) is the universal completion of the natural filtration of R . Consequently, (\mathcal{G}_t) satisfies the usual conditions since (T_t) is continuous. Then, it is straightforward to check that

$$M_t := \int_0^{T_t} \frac{1}{R_u^2 s'(s^{-1}(p(R_u)))} dB_u$$

is a continuous (\mathcal{G}_t) -local martingale with

$$[M, M]_t = \int_0^{T_t} \frac{1}{[R_u^2 s'(s^{-1}(p(R_u)))]^2} du.$$

On the set $[T_t < \infty] = [t < A_\infty]$, the above can be rewritten as

$$[M, M]_t = \int_0^{T_t} \sigma^2(s^{-1}(p(R_u))) dA_u = \int_0^t \sigma^2(X_u) du.$$

Thus, there exists a (\mathcal{G}_t) -Brownian motion, β , such that

$$M_t = \int_0^t \sigma(X_u) d\beta_u.$$

Similarly, on $[t < A_\infty]$

$$\int_0^{T_t} \frac{b(s^{-1}(p(R_u)))}{\sigma^2(s^{-1}(p(R_u))) [R_u^2 s'(s^{-1}(p(R_u))))^2]} du = \int_0^t b(X_u) du.$$

Thus, we have proved on $[t < A_\infty]$

$$X_t = \int_0^t \sigma(X_u) d\beta_u + \int_0^t b(X_u) du.$$

On the other hand, on $[t \geq A_\infty]$, $T_t = \infty$, and $X_t = Y_\infty = s^{-1}(p(R_\infty)) = s^{-1}(p(\infty)) = r$. Furthermore, since $s^{-1} \circ p$ is one-to-one, $A_\infty = \inf\{t \geq 0 : X_t = r\}$. This shows the existence of a weak solution to (2.2) as soon as we verify that $\zeta = A_\infty$. However, this immediately follows from the fact that any diffusion that satisfies (2.2) has the scale and speed given by s and m , respectively, which in turn yields that 0 is an entrance boundary and, therefore, inaccessible.

To show uniqueness let X be a weak solution and $Y = p^{-1}(s(X))$ so that on $[t < \zeta]$

$$Y_t = \int_0^t \frac{s'(X_u)\sigma(X_u)}{s^2(X_u)} dB_u - \int_0^t \frac{(s'(X_u)\sigma(X_u))^2}{s^3(X_u)} du.$$

Consider

$$T_t := \int_0^t \frac{(s'(X_u)\sigma(X_u))^2}{s^4(X_u)} du$$

and its right continuous inverse $A_t := \inf\{s \geq 0 : T_s > t\}$.

As before,

$$T_t = 2 \int_0^r L_t^x \frac{s'(x)}{s^4(x)} dx,$$

where L^x is the diffusion local time at x for X . On the set $[t < \zeta]$, L^x has compact support in $(0, r)$. Thus, $T_t < \infty$ on $[t < \zeta]$ since for $0 < z < u < r$

$$3 \int_z^u \frac{s'(x)}{s^4(x)} dx = \frac{1}{s^3(z)} - \frac{1}{s^3(u)} < \infty.$$

Similarly, T_t is absolutely continuous and strictly increasing on $[0, \zeta)$.

Next observe that

$$- \int_z^r \frac{s(x)}{s'(x)\sigma^2(x)} \frac{(s'(x)\sigma(x))^2}{s^2(x)} dx = - \int_z^r \frac{s'(x)}{s(x)} dx = \infty.$$

Thus, Theorem 2.11 in [13] yields $T_t = \infty$ on $[t \geq \zeta]$. This, in particular, yields that $A_t < \infty$ for all $t < \infty$ and $A_\infty = \zeta$.

Consider $X_t = Y_{A_t}$ and $\mathcal{G}_t = \mathcal{F}_{A_t}$, where (\mathcal{F}_t) is the universal completion of the natural filtration of X . Define the (\mathcal{G}_t) -local martingale

$$M_t = \int_0^{A_t} \frac{s'(X_u)\sigma(X_u)}{s^2(X_u)} dB_u$$

with

$$[M, M]_t = \int_0^{A_t} \frac{(s'(X_u))^2 \sigma^2(X_u)}{s^4(X_u)} du = T_{A_t}.$$

Thus, on the set $[A_t < \zeta]$, $[M, M]_t = t$ as well as

$$- \int_0^{A_t} \frac{(s'(X_u)\sigma(X_u))^2}{s^3(X_u)} du = \int_0^t \frac{1}{X_u} du.$$

Let $\tau := \inf\{t \geq 0 : A_t = \zeta\}$. The above considerations show that on $[0, \tau)$

$$X_t = \beta_t + \int_0^t \frac{1}{X_u} du.$$

Using the continuity of X we also deduce that $X_\tau = Y_\zeta = r$ and X is, therefore, 3-dimensional Bessel process starting at 0 and stopped at r . Since the SDE for the 3-dimensional Bessel process has a unique solution, we deduce that the distribution of (Y_{A_t}) is uniquely identified on $[A_t < \zeta]$. This in turn yields the weak uniqueness of the solutions of (2.2) on $[0, \zeta]$ since A_t is strictly increasing on $[t \leq \tau]$ and $p^{-1} \circ s$ is one-to-one.

If the entrance boundary is the right endpoint, i.e. r , suppose without loss of generality $r = 0$ and consider the diffusion, R , on $(-\infty, 0)$ defined by the SDE:

$$R_t = B_t + \int_0^t \frac{1}{R_s} ds.$$

This is the negative of a 3-dimensional Bessel process and 0 is its entrance boundary. Now, the above arguments can be repeated to show the existence and the uniqueness of the weak solutions of (2.2). \square
